## ABSTRACT

**Background** Precise and accurate field methods for body composition analyses in athletes are needed urgently.

**Aim** Standardisation of a novel ultrasound (US) technique for accurate and reliable measurement of subcutaneous adipose tissue (SAT).

**Methods** Three observers captured US images of uncompressed SAT in 12 athletes and applied a semiautomatic evaluation algorithm for multiple SAT measurements.

**Results** Eight new sites are recommended: upper abdomen, lower abdomen, erector spinae, distal triceps, brachioradialis, lateral thigh, front thigh, medial calf. Obtainable accuracy was 0.2 mm (18 MHz probe; speed of sound: 1450 m/s). Reliability of SAT thickness sums (N=36): R<sup>2</sup>=0.998, SEE=0.55 mm, ICC (95% CI) 0.998 (0.994 to 0.999); observer differences from their mean: 95% of the SAT thickness sums were within ±1 mm (sums of SAT thicknesses ranged from 10 to 50 mm). Embedded fibrous tissues were also measured.

**Conclusions** A minimum of eight sites is suggested to accommodate inter-individual differences in SAT patterning. All sites overlie muscle with a clearly visible fascia, which eases the acquisition of clear images and the marking of these sites takes only a few minutes. This US method reaches the fundamental accuracy and precision limits for SAT measurements given by tissue plasticity and furrowed borders, provided the measurers are trained appropriately.

## BACKGROUND

Body composition has a large impact on health and performance. In aesthetic sports, weight category sports and gravitational sports (in which body weight influences performance, eg, ski jumping, long distance running, etc), many athletes reduce weight rapidly or maintain an extremely low body weight or fat mass in order to gain a competitive advantage. Weight, fatness, energy intake and energy expenditure are closely related to each other. Therefore, extreme weight changes, very low body weight,

extremely low body fat content, loss of tissue or insufficient bone mineral density are common in many weight sensitive sports.<sup>1–5</sup> This may induce severe medical problems,<sup>1 5–7</sup> and instead of the assumed competitive advantage, severe and long-lasting performance setbacks may result.<sup>8–11</sup> The health of the athlete is a precondition for optimum performance. Protecting the health of athletes and optimising their performance both depend on the availability of accurate, precise and valid methods for the assessment of body composition.<sup>12 13</sup>

Recently, the IOC working group on Body Composition, Health and Performance presented a discussion paper on how to minimise risks for athletes in weight sensitive sports.<sup>5</sup> Currently, there are no generally accepted lower limits of weight or fat mass for male and female athletes that can be used as scientifically based threshold values for optimal performance, or for raising the alarm, or for removal of athletes from competition. There are two reasons for this unsatisfactory situation: first, valid methods with sufficient accuracy for body composition assessment in athletes that are applicable in the field do not exist and second, interpretation of body composition data of athletes in various sports is a complex task, particularly because individual differences as well as general sexual dimorphism underpins differences that require consideration.

Body composition data must be seen in the context of other health parameters.<sup>5</sup> Longitudinal changes in body mass (m) and body composition should be followed accurately and precisely for the assessment of the health risks associated with precompetition manipulation of body mass.<sup>5</sup> Subcutaneous adipose tissue (SAT) measurement using skinfolds has a long tradition, but the accuracy obtainable with this technique is limited because skin and SAT are measured together in a compressed state without considering the compressibility and viscous-elastic behaviour at the individual measurement sites.<sup>12–14</sup>

Recently, a novel ultrasound (US) technique for measurement of SAT and embedded fibrous structures has been introduced.<sup>12–15</sup> This US technique avoids

the tissue compression and movement that occurs when using skinfold callipers and employs a recently developed image evaluation procedure for multiple thickness measurements of SAT layers.

## AIMS AND CONTENTS

This US technique and the obtainable accuracy of tissue thickness measurements is analysed in part A. The introduction of a standard set of sites that fulfil the criteria for accurate and reliable measurements of SAT thickness is the content of part B, and interobserver reliability results obtained with this new set of sites in a group of competitive athletes are described in part C. Additional important information on the standardised application of this method for measuring uncompressed SAT thickness and on the interobserver results can be found in the online supplementary appendix.

## PART A: US TECHNIQUE AND ACCURACY

### B-mode US imaging

B-mode (brightness mode) US images are generated by sequences of US beams which penetrate the tissue to create an image in which the brightness of the screen corresponds to the echo intensity in the plane of the scan. The principle of US imaging is the pulse-echo technique. A short pulse (several wavelengths long) is applied and travels with the speed of sound ( $c$ ) in a given tissue. Diagnostic US systems conventionally use  $c=1540$  m/s for calculating the distance ( $d_{US}$ ) from the surface of the probe to the boundary between two tissues. The speed of sound in adipose tissue is lower than that in other soft tissues (1450 m/s).<sup>16 17</sup>

### Standardised US imaging of SAT

US was applied to measure subcutaneous fat as early as 1965,<sup>18</sup> and many applications followed<sup>19–24</sup> in which the potential of this method was identified. A brief review of the history of US applied to measure body fat can be found in Müller *et al.*<sup>14</sup> A novel approach for avoiding measurement errors due to high compressibility of fat<sup>14 25</sup> and a semiautomatic image evaluation procedure designed to minimise measurement errors have recently been published.<sup>12 14 15</sup> Since SAT is highly compressible, the US probe (transducer) has to be placed over a given site without any pressure. This is obtained by using a thick layer of US gel between the probe and the skin (a 3–5 mm thick gel layer should be seen above the skin in the US image). According to the standardised approach applied here, US measurements are made with the participant lying in a supine, prone or rotated position. A diagnostic US system (*GE Logic e*) with a linear probe operated at 18 MHz (in the harmonic mode) was used for the SAT images in this publication (axial resolution: about 0.10–0.15 mm). The application of the US measuring technique at the individual sites is described in part B (table 1). Important points for avoiding errors when using this standardised US method to measure SAT can be found in online supplementary appendix, part A.

### Accuracy of US thickness measurements

Diffraction and technically obtainable minimum pulse length limit lateral and axial resolution approximately to the wavelength used. Diagnostic US probes (transducers) use frequencies from 3 to 22 MHz, which corresponds to a wavelength in soft tissue of 0.5–0.07 mm. US attenuation increases with increasing frequency—typical investigable depths are between 10 mm (22 MHz) and 200 mm (3 MHz). For studies of fat patterning in athletes or other individuals who have only thin layers of SAT, high frequencies (9–18 MHz) are recommended to obtain US images with high resolution. This enables thickness

measurements with an accuracy that is limited only by furrowed borders and plasticity of the tissues. When using 18 MHz, the border resolution error due to the US resolution limit is about 0.1 mm on each side of the SAT. The calculated distance is the sound speed multiplied by half the echo time. Therefore, any deviation of the sound speed used by the US system from the actual sound speed in the tissue adds to the distance measurement error. In obese persons, where SAT is several centimetres thick, the border resolution error can be neglected; accuracy would be limited by incorrect sound speed rather than by US resolution. For instance, when measuring a 100 mm thick SAT layer, it does not matter whether the borders are detected with a resolution of 0.1 or 0.3 mm (corresponding to 0.1%, or 0.3%, respectively). Therefore, a lower frequency (which is necessary for thick tissue layers) will not reduce accuracy substantially, provided the speed of sound is set correctly.

In the distance evaluation algorithm (*FAT Software*; *rotosport.com*) developed for multiple tissue thickness measurements, the sound speed can be set appropriately for any biological tissue. Thus, the technical measurement error can be kept very low; this also holds true in thick fat layers. The limiting factors for accuracy are intrinsic in the tissue: furrowed tissue borders and viscous-elastic features of SAT. Since accuracy is limited primarily by these biological factors, and since precision limitations (reliability), not technical US accuracy limitations, will be the dominating factor of the overall error in most cases, it is of paramount importance to minimise these influences by standardising measurement sites and technique (see part B). An example analysis of technically obtainable measurement accuracy can be found in online supplementary appendix, part A. Interobserver reliability is analysed quantitatively for a sample of athletes in part C of this publication.

### Semiautomatic multiple thickness measurement of SAT

For measurement of a series of thickness values in a given US image, an image segmentation algorithm for detecting the SAT contour was applied<sup>14</sup> and US images were evaluated by means of a semiautomatic distance measurement algorithm (*FAT Software*, *rotosport.com*). Sound speed was set to 1450 m/s in the evaluation software for distance calculation in adipose tissue.<sup>16 17</sup> Usually 50 to 300 individual thickness measurements resulted from one image (depending on the selected region of interest). Mean, SD, median, minimum and maximum values were automatically calculated. The tissue segmentation was controlled visually and, if necessary, parameters that determine the accepted segment inhomogeneity could be set manually to optimise SAT contour detection. The software also enables an operator to distinguish between distances in which embedded tissues (eg, fibrous structures) are included ( $d_{INCL}$ ) or excluded ( $d_{EXCL}$ ). The thickness of the embedded structures is also determined:  $d_{ES}=d_{INCL}-d_{EXCL}$ .

## PART B: STANDARDISATION OF US SITES AND PROCEDURE

A new set of sites that provide anatomical and image clarity is presented in this part. An accurate description of these sites and the development of a basis for standardising this US measurement technique are the core of this section.

The US approach to measure SAT outlined in part A was first applied to the set of sites used for skinfold measurement (International Society for the Advancement of Kinanthropometry—ISAK sites), but several of these skinfold sites do not allow clear US images,<sup>14 15</sup> and the marking of ISAK sites requires specific knowledge of anatomy and detailed anthropometry training.<sup>26 27</sup> ISAK sites were defined for skinfold studies, but do not optimally fulfil the criteria for US

**Table 1** Description of ultrasound (US) sites and measurement procedure (see [figure 1](#))

Site name	Description of the sites Marking is done in a standing or sitting position, on the right side of the body; see <a href="#">figure 1</a> . All distances (d) are percentages of body height h	Notes on US image capture All US measurements in a lying position! Always use a thick layer of US gel (at least 3–5 mm)
UA Upper abdomen	<ol style="list-style-type: none"> <li>1. Mark a vertical line at a distance <math>d=0.02</math> h (ie, 2% of body height h) lateral to the centre of the umbilicus (<i>omphalion</i>)</li> <li>2. Project vertically and mark a horizontal line at <math>d=0.02</math> h superior to the <i>omphalion</i> (<a href="#">figure 1A</a>). (In case this site is above a tendinous inscription of the rectus abdominis (where subcutaneous adipose tissue (SAT) is thicker), move the probe some mm to the end of this inscription and measure the thickness there)</li> </ol>	Lying in a supine position Have the participant stop breathing at mid-tidal expiration and then capture the image
LA Lower abdomen	<ol style="list-style-type: none"> <li>1. The same line (1) as for the upper abdomen</li> <li>2. Project vertically and mark a horizontal line at <math>d=0.02</math> h inferior to the <i>omphalion</i>. Measure always exactly at this point (<a href="#">figure 1A</a>)</li> </ol>	Lying in a supine position Have the participant stop breathing at mid-tidal expiration and then capture the image
EO External oblique (optional site)	<ol style="list-style-type: none"> <li>1. Locate and mark the anterior superior iliac spine (ASIS).</li> <li>2. The participant assists by holding the end of the tape at the apex of the costal arch at the inferior margin of the sternum (where it meets the xiphoid process). The participant looks ahead!</li> <li>3. Draw a line from the ASIS in the direction of the costal arch</li> <li>4. Mark a perpendicular line at <math>d=0.02</math> h from ASIS (<a href="#">figure 1A</a>)</li> </ol>	Lying in a supine position Capture the image with the probe held in the direction of the perpendicular line
ES Erector spinae	<ol style="list-style-type: none"> <li>1. Mark a transverse line at <math>d=0.14</math> h above the solid surface (table) on which the person is sitting in a stretched upper body position with thighs horizontal and legs unsupported</li> <li>2. Mark the site at <math>d=0.02</math> h lateral to the spinous process of the vertebra (<a href="#">figure 1C</a>)</li> </ol>	Lying in a prone position
DT Distal triceps	<ol style="list-style-type: none"> <li>1. Put the lower arm on a support surface (table) with the hand in the mid-prone position; mark a vertical line on the most posterior aspect of the arm.</li> <li>2. Mark the site on the vertical line at a distance from the surface of <math>d=0.05</math> h (<a href="#">figure 1D</a>)</li> </ol>	Lying in a prone position Capture the image with the dorsal surface of the hand on the table. Make sure the probe orientation is perpendicular to the skin
BR Brachioradialis	<ol style="list-style-type: none"> <li>1. The participant puts the forearm with the hand in the mid-prone ('shake-hands') position on a support table and contracts the brachioradialis (eg, against a resistance provided by the hand of the measurer), <a href="#">figure 1D</a>.</li> <li>2. Draw a longitudinal line on the most anterior surface of the brachioradialis muscle</li> <li>3. Mark a transverse line at a distance <math>d=0.02</math> h distally from the anterior surface of the biceps brachii tendon (press the end of the metre rod onto the stretched tendon). Project this line transversely to intersect with the longitudinal line (<a href="#">figure 1D</a>)</li> </ol>	Lying in a supine position Take the image with the arm in a mid-prone position and in contact with the thigh (muscles of the arm are relaxed) Avoid imaging the vein in case there is one in the vicinity
FT Front thigh	<ol style="list-style-type: none"> <li>1. Put the foot on the anthropometric box which is placed in front of a wall such that the thigh is horizontal and the big toe and the knee touch the wall.</li> <li>2. Mark the site at a horizontal distance <math>d=0.14</math> h from the wall (<a href="#">figure 1E</a>)</li> </ol>	Lying in a supine position.
MC Medial calf	<ol style="list-style-type: none"> <li>1. Place the foot on the anthropometric box such that the thigh is horizontal and the leg vertical</li> <li>2. Mark the site at <math>d=0.18</math> h above the surface at the most medial aspect (use a ruler to determine the most medial aspect when looking vertically down) (<a href="#">figure 1F</a>)</li> </ol>	Lying in a rotated position Participant rolls onto the right side with the right knee at a 90° angle so that the lateral aspect of the right leg is supported
LT Lateral thigh	<ol style="list-style-type: none"> <li>1. Draw a horizontal line on the lateral side of the thigh at the height of the gluteal fold (at the height of the fold at the most dorsal aspect of the thigh);</li> <li>2. Mark the site on this line at the midpoint of the sagittal thigh diameter (<a href="#">figure 1G</a>). Use a calliper for (1) and (2)</li> </ol>	Lying in a rotated position Participant rolls onto the left side with both knees at a 90° angle, with the right leg over the left leg

measurement of uncompressed SAT. Therefore, identification of sites that can be found easily and reproducibly, also by those who lack specific anthropometry experience, was necessary for SAT patterning studies using diagnostic US. The search for new sites was determined by the following criteria: the set of sites represents trunk, arms and legs; sites can easily be marked with high precision after 1 h of training; all distances necessary to define the new sites are relative to the person's body height; anatomical structures are easily identifiable in the US image (dermis, SAT, fascia of the muscle); and SAT thickness does not change much in the vicinity of the site.

### Description of standard sites selected for US measurements of SAT patterning

[Table 1](#) describes the basic set of eight sites that were selected for analysis of SAT patterning. All sites are marked on the right side of the body ([figure 1A–G](#)). The table also includes notes on how to take the US images at the individual sites. Sites UA (upper abdomen), LA (lower abdomen) and EO (external oblique) are marked in the standing position ([figure 1A](#)). In the fat patterning studies described in this publication, the EO site

was used. This site is close to the supraspinale ISAK site, but recent experience has shown that SAT layers are very thin at this site in athletes and do not contribute substantially to the sum of SAT thicknesses, and marking takes too much time and can be difficult in obese persons. Therefore, EO should only be used as an optional site in future studies. The site ES (erector spinae) is marked in the stretched sitting position ([figure 1C](#)), while sites DT (distal triceps) and BR (brachioradialis) are marked with the forearm supported on a table and the arm held vertically ([figure 1D](#)). The site FT (front thigh) is marked with the foot placed on an anthropometric box which is placed in front of a wall such that the thigh is horizontal and the big toe and the knee touch the wall ([figure 1E](#)). Site MC (medial calf) is marked with the right foot on a box of appropriate height such that the upper leg axis is horizontal and the lower leg vertical ([figure 1F](#)). LT (lateral thigh) should be used in the core set of eight sites to determine SAT thickness in this fat depot area of the thigh. The site is marked in the standing position at the midpoint of the sagittal thigh diameter at the height of the gluteal fold (the height at the most dorsal aspect is used in case the fold is not horizontal).

**Figure 1** Ultrasound sites. (A and B) Survey of the US sites described in [table 1](#). (C–G) Body positions when marking these sites. (C) shows how to mark the ES site, and also how to measure sitting height (s).

It is important that the participant looks forward at all times when the trunk sites are marked because movements of the head affect marking accuracy. It should also be noted that, while marking is done in a standing or sitting position, all US measurements are made with the participant lying in a supine, prone or rotated position, as described in [table 1](#).

### Examples of fat patterning results

A typical US image from the MC site is shown in [figure 2](#). Below the black band corresponding to the gel layer between the probe and skin are the epidermis and dermis, and the dark (almost black) SAT layer (interrupted by a fibrous structure in this case); the fascia of the muscle, and the muscle underneath can be identified easily. The borders of SAT (skin and fascia) are white bands without interruption (no ‘black holes’ are included in the white bands—this is a necessity for the semiautomatic image segmentation).

A series of US images of a female gymnast, after a phase of reduced training, is shown in [figure 3](#), while [figure 4A](#) displays the corresponding SAT thickness values, and [figure 4B](#) shows the SAT pattern of the athlete 4 months before when she was in full training. In [figure 3](#), the structures of relevance are easily identifiable: skin, SAT and muscle fascia. At the LA, an intermediate fascia structure is visible (Camper’s fascia). In order to determine the precise location of the muscle fascia (the lower border of SAT) in this case, the US probe was applied with varying pressure on the skin (with just a thin layer of gel) before starting the measurement without compression (using a thick layer of gel). The compressibility of SAT is higher than that of muscle tissue and the associated changes in the image due to changing compression enabled the observer to distinguish clearly between them. At the ES site, the thicker skin of the posterior trunk can be seen below the black layer of gel, followed by an almost homogeneous (almost black) SAT layer, and finally the fascia above the muscle appears as a light band. An intermediate fascia is present in this athlete at the FT and MC sites. The seeds from which the SAT contour detection algorithm started are also shown in the images.

Examples of survey plots of the fat patterning in five athletes are shown in [figure 4A–F](#). [Figure 4A](#) represents SAT patterning in the female gymnast whose US image series is displayed in

[figure 3](#).  $D_{INCL}$  changed by 62% during a phase of reduced training. This large increase in the SAT thickness sum was associated with a weight gain of only 1.4 kg. [Figure 4C,D](#) show SAT patterning of two female swimmers; both were preparing for the World Championships in 2015. Between them, SAT thickness sums  $D_{INCL}$  differed by 330% (18.0 and 60.6 mm, respectively). [Figures 4E](#) (male world champion in swimming) and 4F (international level male gymnast) show extremely low SAT values: the sums of the eight sites  $D_{INCL}$  are 9.1 and 6.3 mm, respectively (this equals a mean SAT thickness in these athletes of only 1.1 and 0.8 mm). Body mass index (BMI) does not correlate with sums of SAT thicknesses in the athletes whose SAT thicknesses are shown in [figure 4](#).

### Discussion of the site selection and standardisation process

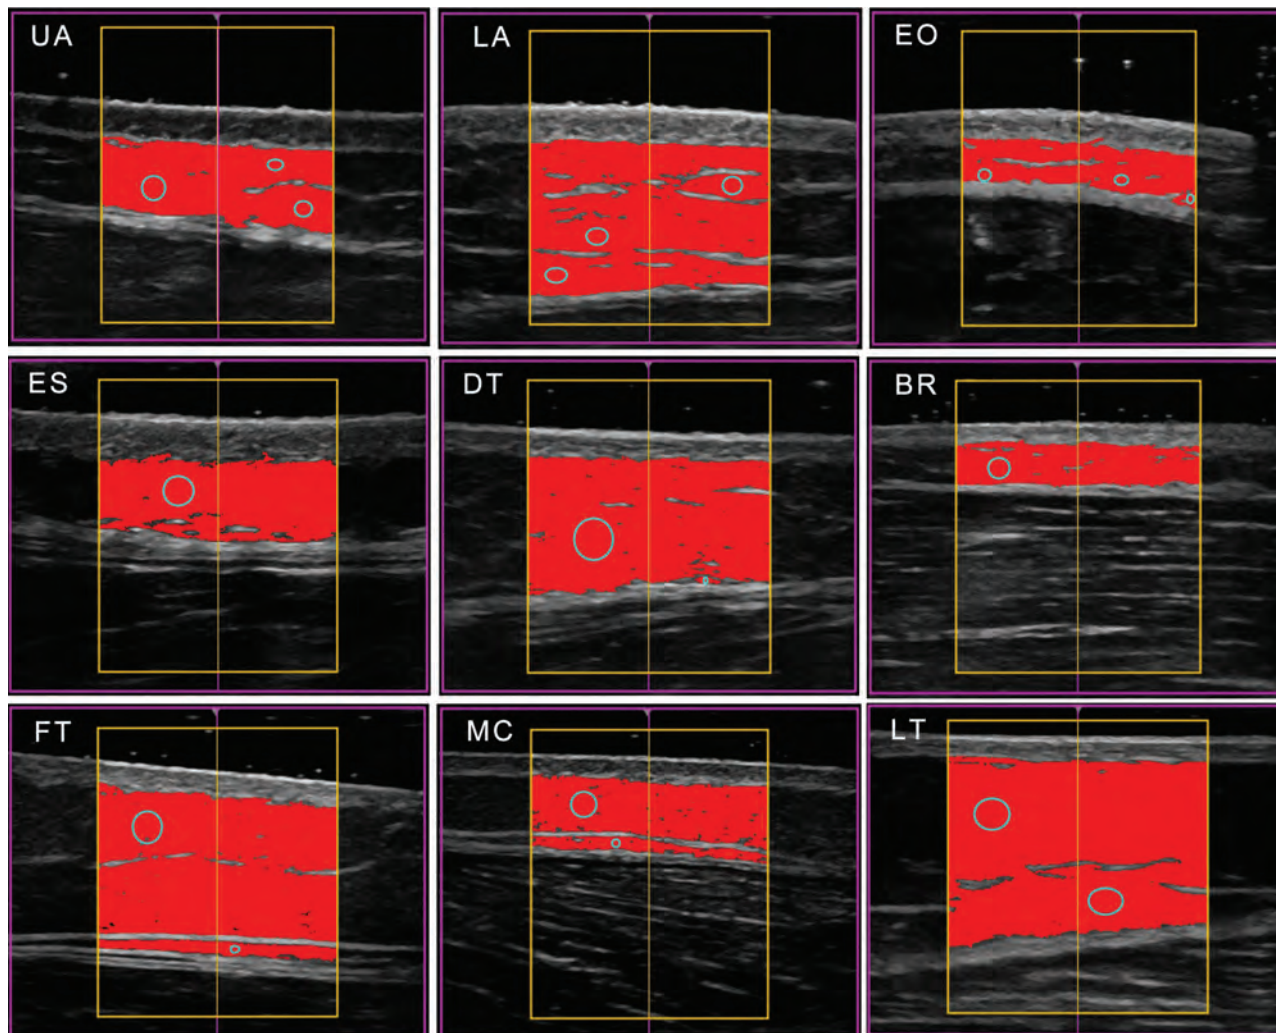

Final selection of the core sites for US SAT patterning studies was a long process. We began with the eight ISAK sites for skinfold measurements because of the existing experiences at these sites.<sup>19 26–28</sup> A comparison with ISAK skinfolds showed the low validity of skinfold thickness measurements for determining SAT thickness because of the high compressibility of fat.<sup>14</sup> Such accuracy limitations due to the varying compressibility of SAT are to be expected at all other sites that have been used for skinfold measurements as well.<sup>29</sup> Using the individual body height (h) as the distance reference for all sites increases the marking precision substantially and is better than using fixed distance values for all persons independent of their differing body dimensions. Further considerations that influenced the site selection process can be found in online supplementary appendix, part B.

The predictive value of SAT thickness data obtained by US in terms of total body fat remains to be analysed within the framework of validation studies using multicomponent body composition models.<sup>12 30</sup> The obtainable accuracy (see part A) and precision (see part C) support the expectation that total body fat assessment based on this US technique should result in better adiposity estimates than that based on other field methods, particularly for athletes and other lean individuals in whom internal fat is low.

There is a potential to replace other field methods because of the high accuracy and precision obtainable with US; however, it will take some time until comprehensive reference data become available for comparing and interpreting the results obtained in

**Figure 2** Typical example of an ultrasound image of SAT site: medial calf (MC). Structures of relevance for US image evaluation are marked. In the right-hand image, the detected SAT region is displayed in white. Within the region of interest, the evaluation algorithm measured automatically 280 SAT thickness values (along 280 vertical lines in the image). Means:  $D_{INCL}=1.97 (\pm 0.14)$  mm,  $D_{EXCL}=1.62 (\pm 0.16)$  mm, and the difference  $D_{ES}=0.35$  mm, which represents the mean thickness of the embedded (fibrous) structures.  $D_{INCL}$ : thickness with fibrous structures;  $D_{EXCL}$ : thickness without fibrous structures. Sound velocity was set to  $c=1450$  m/s. Image depth was 15 mm. SAT, subcutaneous adipose tissue.

**Figure 3** Series of SAT measurements at the sites described in [table 1](#). Typical US images captured for fat patterning analysis. A linear probe (GE, L18) operated at 18 MHz (in harmonic mode) was used. Image depth was 20 mm. Camper's fascia is visible at the lower abdomen (LA) site. Mean SAT thicknesses (in mm) are (compare to figure 4A): UA: 4.26, LA: 8.30, EO: 2.44, ES: 4.29, DT: 7.11, BR: 2.24, FT: 8.99, MC: 4.04, which sum to  $D_{INCL}=41.67$  mm in this example. Thickness at LT: 9.85 mm. The mean thicknesses without fibrous structures are: UA: 4.09, LA: 7.30, EO: 2.21, ES: 4.04, DT: 6.84, BR: 2.13, FT: 8.30, and MC: 3.55, and the sum  $D_{EXCL}=38.47$  mm; LT: 9.43 mm. UA, upper abdomen; LA, lower abdomen; EO, external oblique; ES, erector spinae; DT, distal triceps; BR, brachioradialis; FT, front thigh; and MC, medial calf; LT, lateral thigh; SAT, subcutaneous adipose tissue.

various groups of athletes. Until then, other field methods may remain in parallel use, although their measurement accuracy does not reach the level desired for medical diagnoses, performance optimisation strategies or 'no-start' decisions.

### PART C: INTEROBSERVER RELIABILITY

A comparison of the results obtained by three observers using the standardised US method described in part A and part B is presented in this section. Three observers measured the eight sites each in each of 12 athletes. Each observer evaluated his own 96 images.

### METHODS

#### US sites for measurement of SAT patterning

All sites were marked on the right side of the body. The sites used for this interobserver study were: UA, LA, EO, ES, DT, BR, FT and MC. LT was not used here.

#### Anthropometry

Anthropometric data included: m, h, sitting height (s)—measured in the fully stretched position, ( $BMI=m/h^2$ ) and the mass

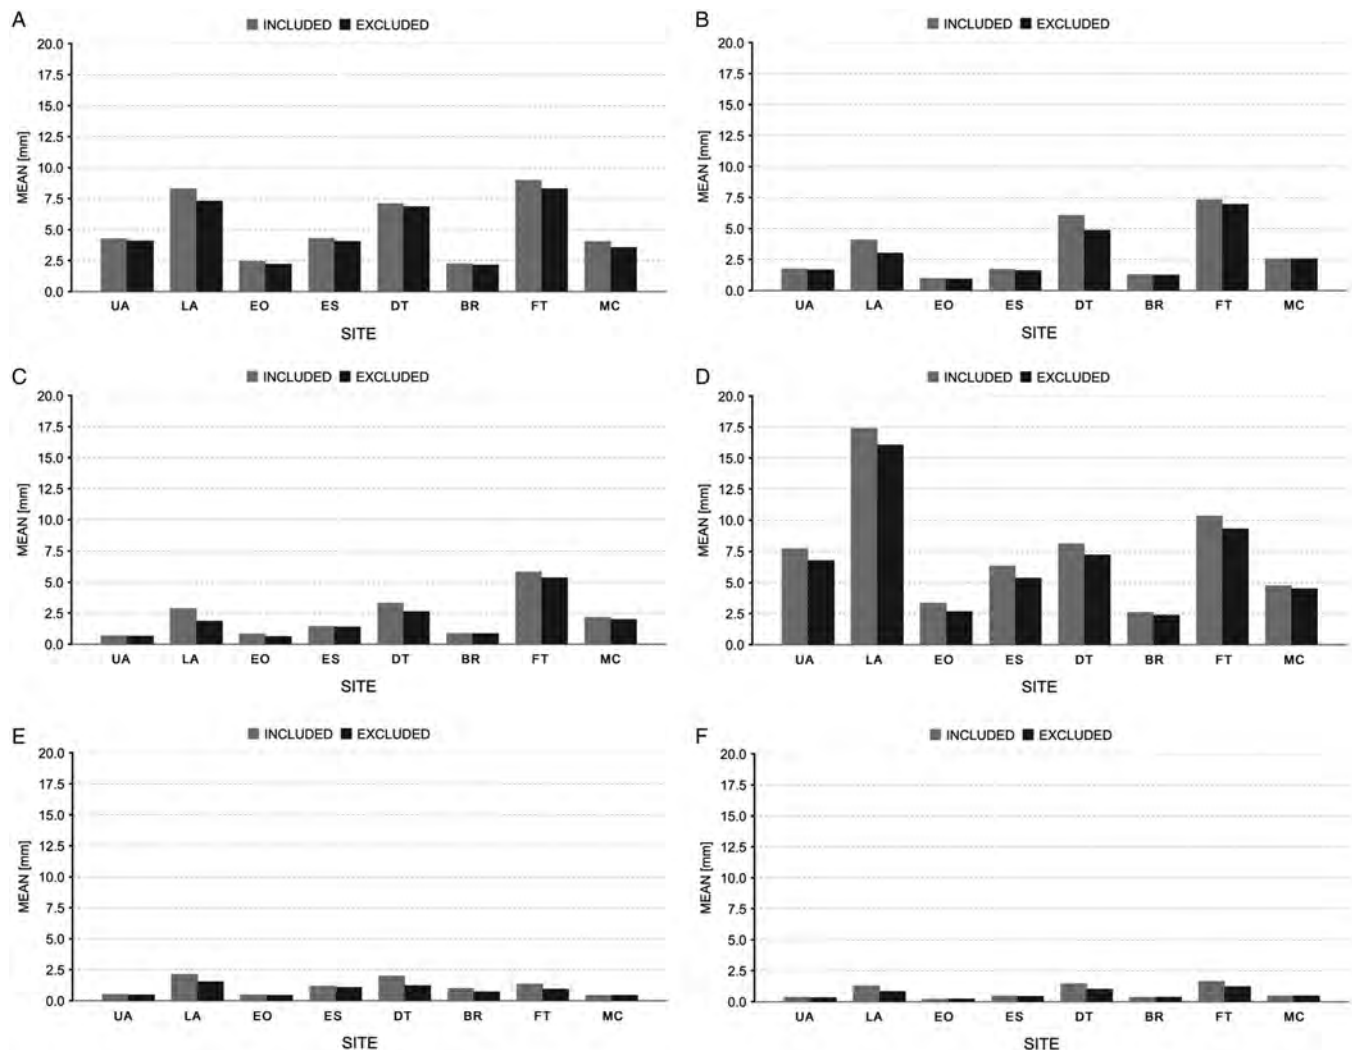

index ( $MI_1$ ).  $MI_1$  considers individual sitting height:  $MI_1=0.53$  m/(hs).<sup>3 4 31</sup> For  $s/h=0.53$ ,  $MI_1$  equals the BMI.

#### Statistics, participants and observers

Values are presented as means $\pm$ SDs and distribution of data is shown in box plots. Further information on statistical methods, participants and observers can be found in online supplementary appendix, part C.

### RESULTS

[Figure 5](#) shows the three observers' individual SAT thickness sums  $D_{INCL}$  obtained from the eight sites plotted over the mean value of the three observers' sums (in a given athlete). Values are presented in [table 2](#). Online supplementary figure 8 and supplementary table 4 show the results for  $D_{EXCL}$ . Sums of SAT thickness measurements with the embedded fibrous structures included are termed  $D_{INCL}$ , while  $D_{EXCL}$  denotes measurements with the fibrous structures excluded (subtracted). Statistical characteristics for  $D_{INCL}$  are:  $R^2=0.998$ ,  $ICC=0.998$ ,  $SEE=0.55$  mm, and for  $D_{EXCL}$ :  $R^2=0.997$ ,  $ICC=0.996$ ,  $SEE=0.66$  mm. Deviations for  $D_{INCL}$  were slightly smaller because there is just one upper border and one lower border to

**Figure 4** Survey plots of fat patterning in five athletes. The columns show the mean values of the semi-automatic multiple thickness measurements for the eight US sites. The mean thickness value of the SAT thickness in a given ultrasound image (within the region of interest) is termed  $D_{INCL}$  (grey) when fibrous structures are included, and it is termed  $D_{EXCL}$  (black) when fibrous structures are subtracted. A: Female artistic gymnast in a phase of reduced training ( $m=59.6$  kg,  $BMI=20.5$   $kgm^{-2}$ ,  $D_{INCL}=41.7$  mm). B: The same female gymnast 4 months previously when in full training ( $m=58.2$ ,  $BMI=20.0$   $kgm^{-2}$ ,  $D_{INCL}=25.8$  mm). C and D: Female swimmers ( $m, h, BMI, D_{INCL}$ : 59.4 kg, 1.685 m; 20.9  $kgm^{-2}$ , 18.0 mm; 67.0 kg, 1.830 m, 20.0  $kgm^{-2}$ , 60.6 mm); both were in preparation for the 2015 world championships. E: World class swimmer ( $BMI=23.7$   $kgm^{-2}$ ,  $D_{INCL}=9.1$  mm). F: National level artistic gymnast ( $BMI=21.4$   $kgm^{-2}$ ,  $D_{INCL}=6.3$  mm). UA, upper abdomen; LA, lower abdomen; EO, external oblique; ES, erector spinae; DT, distal triceps; BR, brachioradialis; FT, front thigh; and MC, medial calf; LT, lateral thigh.

be determined by the algorithm, whereas for  $D_{EXCL}$ , there are several additional borders to be determined to measure the additional thicknesses of embedded structures.

Box plots in [figures 6A and 6B](#) represent the absolute values of the individual observer deviations from their means. The three observers measured the sums of eight sites in 12 athletes, resulting in 36 comparisons of SAT thickness sums. Median scores of the absolute deviation values  $ABS(\Delta_{INCL})$  and  $ABS(\Delta_{EXCL})$  were 0.24 and 0.36 mm, respectively. Maximum deviations of individual observer sums of thicknesses were:  $ABS(\Delta_{INCL,max})=1.50$  mm and  $ABS(\Delta_{EXCL,max})=1.58$  mm. There are two outliers in each box plot. A comparison of the US images from the three observers showed that an intermediate fascia (Camper's fascia) instead of a muscle fascia had erroneously been used by one observer as the lower border of SAT. The SDs of the observer differences from the mean were:  $SD(\Delta_{INCL})=\pm 0.54$  mm, and  $SD(\Delta_{EXCL})=\pm 0.65$  mm, respectively. The 1.96-SD values, representing 95% of measurements, were  $\pm 1.1$

and  $\pm 1.3$  mm, respectively (compare with online supplementary figures 9A and 9B).

Box plots in online supplementary figures 9C and 9D represent the distribution of the relative errors  $\Delta_{rel}=100\cdot\Delta/D_{MEAN}$  (in per cent). For  $\Delta_{INCL,rel}$ , the median is 1.0%, maximum is 3.9%. For  $\Delta_{EXCL,rel}$ , the median is 1.6%, maximum is 5.3%. The SAT thickness sums for  $D_{INCL,MEAN}$  ranged in this group of athletes from 10.2 to 51.2 mm, and for  $D_{EXCL,MEAN}$  from 7.3 to 46.7 mm.

The analysis of observer differences at the eight individual sites is described and illustrated in online supplementary figure 10A–D.

## DISCUSSION

### Interobserver reliability of SAT thickness measurements: results obtained with the new set of sites compared to previous results with ISAK sites

Precision is influenced by the viscoelastic movements of SAT depending on the actual body position during marking and

**Figure 5** Sums of thicknesses from eight sites measured by the three observers in 12 athletes. The sums  $D$  of the individual observers (in a given participant) are displayed over the mean value of the three observers. Sums of SAT thicknesses with the embedded fibrous structures included ( $D_{INCL}$ ) are shown.  $R^2=0.998$  ( $p<0.01$ ),  $SEE=0.55$  mm,  $ICC=0.998$  (lower 95% CI limit: 0.994; upper 95% CI limit: 0.999). SAT, subcutaneous adipose tissue.

during measuring. Standardising the marking and measuring procedure is therefore important to obtain precise results.

Owing to furrowed borders of SAT, precision depends on orientating and positioning the probe at the centre of the site; otherwise, the US image would map another region of SAT (with the high accuracy as discussed in part A) that may have a different thickness, and a different amount of embedded structures. Therefore, it is essential to use measurement sites where the SAT thickness does not change much in the region surrounding the centre of the site. It is of importance that the investigators are trained to find these sites reliably and to apply the method in the standardised way as described in parts A and B of this publication.

**Table 2** Measurement results for the three observers

Participant	$D_{INCL, MEAN}$	$D_{INCL}$			$\Delta_{INCL}$		
		OBS1	OBS2	OBS3	OBS1	OBS2	OBS3
1	10.23	10.05	10.07	10.57	-0.18	-0.16	0.34
2	13.02	13.11	12.78	13.16	0.09	-0.24	0.14
3	15.81	15.60	15.89	15.94	-0.21	0.08	0.13
4	17.22	16.54	17.27	17.84	-0.68	0.05	0.62
5	21.57	21.21	22.05	21.44	-0.36	0.48	-0.13
6	32.75	33.05	32.62	32.57	0.30	-0.13	-0.18
7	33.05	32.02	33.94	33.20	-1.03	0.89	0.15
8	37.41	36.59	38.22	37.42	-0.82	0.81	0.01
9	38.96	38.71	39.63	38.54	-0.25	0.67	-0.42
10	41.07	40.73	41.09	41.38	-0.34	0.02	0.31
11	46.43	47.85	44.93	46.50	1.42	-1.50	0.07
12	51.23	51.43	51.33	50.94	0.20	0.10	-0.29

Shown are the sums of SAT thicknesses with embedded structures included (in mm) from eight sites obtained by the three observers in 12 athletes, the means of their measurements and the differences of the individual observer measurements from the means.  $D_{INCL, MEAN}$  and  $\Delta_{INCL}=D_{INCL}-D_{INCL, MEAN}$  (compare to figure 5 and online supplementary 9A). SAT, subcutaneous adipose tissue.

**Figure 6A** Observer differences from the mean. Three observer measurements of the sums from the eight sites in each of the 12 athletes ( $N=36$ ). The absolute values of the observer differences (their individual sums from eight sites  $D_{INCL}$  minus the mean of the three observers  $D_{INCL, MEAN}$ ) are used for this box plot:  $ABS(\Delta_{INCL})=ABS(D_{INCL}-D_{INCL, MEAN})$ . Median was 0.24 mm, IQR was 0.46 mm, and maximum deviation from the mean was 1.50 mm.

Comparison of the interobserver studies with ISAK sites and with the new US sites shows that the new sites resulted in much clearer images and higher precision. A detailed comparison of the interobserver reliability obtained with ISAK sites previously<sup>14 15 26</sup> with the results obtained here can be found in online supplementary appendix, part C. Currently, the new sites are being applied within the framework of a multicentre interobserver variability

**Figure 6B** Absolute values of differences (fibrous structures excluded). The absolute values of the individual observer differences (their individual sums from eight sites  $D_{EXCL}$  minus the mean of the three observers  $D_{EXCL, MEAN}$ ) were used:  $ABS(\Delta_{EXCL})=ABS(D_{EXCL}-D_{EXCL, MEAN})$ . Median was 0.36 mm, IQR was 0.57 mm, and maximum deviation from the mean was 1.58 mm.

study under the auspices of the IOC Medical Commission. Comparisons of SAT thickness sums with dual-energy X-ray absorptiometry applied to measure total body fat will also be included in this research.

In the study presented here, the EO site was considered because it is situated close to the ISAK site *supraspinale*. However, marking of EO requires palpating and identifying anatomical bony landmarks, whereas all seven other sites do not. In some cases, this caused problems when marking the site precisely, particularly for heavy athletes and in obese persons. A promising candidate for replacing EO is LT because at this site interesting information concerning fat patterning in different somatotypes and between men and women can be expected,<sup>27–29</sup> and it is easy to mark LT precisely. The LT site also avoids marking problems that can occur at the EO site in participants with very thick SAT layers. The LT site should therefore replace the EO in future investigations.

## SUMMARY AND CONCLUSIONS

All eight new site locations are defined relative to the size of the individual, and a minimum of eight sites are measured to account for inter-individual differences in SAT patterning and for obtaining a sum of SAT thickness which ensures high accuracy and reliability. These new sites optimise the acquisition of clear US images. The orientation of the US probe is approximately parallel with the alignment of the underlying muscle fibres.

To obtain high quality data, observers must participate in a structured training programme that consists of site-marking experience, handling the US system, application of the image segmentation and SAT measurement programme, and guided exercises and interobserver comparisons.

In persons with thick SAT layers, lower frequencies are necessary and they are associated with lower tissue border resolution, but the relative error remains small. Combining the very accurate US method with MRI methods that can be applied to quantify volumes of visceral and abdominal SAT may be the key for developing more enhanced body composition reference methods.<sup>32–35</sup> Furthermore, validation studies against multicomponent models<sup>12 30</sup> are necessary to resolve the question whether SAT thickness measurements with the fibrous structures included or excluded will result in better estimates of total body fat. The main advantages of this novel US technique over other body composition methods are:

- ▶ The selected sites represent the relevant body segments: upper and lower abdomen, back, upper arm and forearm, and lateral, upper and lower leg
- ▶ High measurement accuracy of about 0.2 mm (18 MHz linear probe) can be obtained when the tissue's speed of sound is set correctly
- ▶ Adipose tissue compression is avoided by using a thick layer of US gel (in addition, the person is asked to stop breathing during image capture)
- ▶ High precision results when measurers are trained to apply the standardised technique appropriately (95% of SAT thickness sums were within  $\pm 1$  mm)
- ▶ Visual control of the semiautomatic measurement algorithm eliminates errors of the automatic contour detection
- ▶ The automatic measurement of many thickness values in one image, and the possibility to include or exclude embedded structures like fibrous tissues in the thickness values and to quantify their depth
- ▶ Appropriate for use in the field when employing portable US systems

- ▶ The technique has minimal subject involvement, does not require ionising radiation and can be applied to children, adolescents and adults
- ▶ Accommodation of a wide range of adiposity from lean to obese participants
- ▶ Applying this standardised technique will make results of different working groups directly comparable, and will facilitate the collation of a reference database

At this time, the US technique has the following limitations:

- ▶ As with skinfolds, this US technique only samples the SAT and does not measure fat stored in the deeper regions
- ▶ Equipment costs are greater than for skinfolds, but decreasing prices of US systems may accelerate the replacement of other field methods commonly used in sports medicine<sup>36 37</sup>
- ▶ Since this is a new measurement approach, it will take some time until a comprehensive data pool can be collated. Such a data pool is needed to provide a basis for sports medicine decisions and performance optimisation strategies
- ▶ The marking, image capture and evaluation of eight sites take about 20 min (which is comparable to skinfolds when eight sites are measured in triplicate).

This US method enables highly sensitive SAT comparisons between individuals and between groups. Various kinds of cross-sectional and longitudinal studies can now be conducted such that small adiposity changes can be detected with the sensitivity that this US technique provides.

## What are the findings?

- ▶ The standardised ultrasound (US) measurement technique enables subcutaneous adipose tissue (SAT) patterning studies with very high accuracy and precision. When sound speed is set correctly, thickness measurement accuracy is approximately 0.2 mm (18 MHz linear US probe).
- ▶ In athletes, the sum of SAT thicknesses of eight sites varies between a few mm and more than 100 mm. In the interobserver study presented here, it was found that the deviations of three observers' individual measurements from the mean were smaller than  $\pm 1$  mm in 95% of cases (thickness sums ranged in this group from 10 to 50 mm). Therefore, differences of 2 mm (of the sum from eight sites) could reproducibly be distinguished.
- ▶ The previously used ISAK sites (International Society for the Advancement of Kinanthropometry), which were defined for skinfold measurements, are not well suited for US imaging of SAT and are therefore replaced by this new set of sites which fulfil the criteria for reproducible and accurate US measurements.
  - UA (upper abdomen),
  - LA (lower abdomen),
  - ES (erector spinae),
  - DT (distal triceps),
  - BR (brachioradialis),
  - LT (lateral thigh),
  - FT (front thigh),
  - MC (medial calf).
- ▶ All new sites overlie muscle with a clearly visible fascia, away from other complex structures, thus easing the acquisition of US images. SAT layers show little variation in thickness in the vicinity of these selected sites; this is an important criterion because the major part of measurement deviations is due to unavoidable position changes of the US probe when measurements are repeated.
- ▶ Fibrous structures embedded in SAT can also be quantified.

## How might it impact on clinical practice in the future?

- ▶ This new US method is capable of measuring SAT layers without compression and with high accuracy and precision. Therefore, it enables longitudinal studies of fat patterning changes and athlete comparisons with a sensitivity not reached by any other technique.
- ▶ This US measurement approach will complement other laboratory methods, and it is also applicable for use in the field.
- ▶ There is potential for US to replace other field methods because of its high accuracy and precision; however, it will take some time until comprehensive reference data of various groups of athletes will be available.
- ▶ This US technique provides the highest technically obtainable accuracy for SAT thickness measurement, which is limited only by biological factors. The new site definitions improve the application of US and result in good reliability.
- ▶ The semiautomatic image evaluation also allows the quantitative determination of the amount of fibrous structures embedded in SAT, which varies largely from one site to another and between individuals.
- ▶ Owing to the high accuracy of image evaluation, this US method can also be applied to optimise the image segmentation algorithms of other imaging techniques like MRI or CT.
- ▶ This emerging measurement technique has the potential to spread rapidly because prices of high-quality US imaging systems have decreased markedly in recent years.
- ▶ The eight selected sites can be used as a standard set of sites for pooling data on SAT patterning in athletes (and in untrained persons) which will be valuable for comparisons of SAT layers among individuals and between groups.
- ▶ Specific training of US imaging and evaluation of SAT is necessary to obtain high reproducibility and accuracy of measurements. Two days of training are sufficient for measurers who have had some prior US imaging experience.

**Acknowledgements** The authors would like to thank the IOC Medical Commission for supporting the collaboration of the authors.

**Contributors** All authors contributed to the selection and testing of appropriate sites for US measurement of SAT patterning and supported the finalisation of the manuscript. This ultrasound approach to determine SAT patterning and the semiautomatic US image segmentation and thickness evaluation technique was developed in Graz by WM, HA, PK and AF-R. The research was conducted by WM who also prepared the manuscript.

**Funding** The cooperation of the Adhoc Working Group on Body Composition, Health and Performance was supported by the Medical Commission of the IOC.

**Competing interests** The evaluation software developed for this US technique for multiple tissue thickness measurements is commercially available, and WM, HA, AF-R and PK will participate in the returns.

**Patient consent** Obtained.

**ABBREVIATIONS:**

OBS	Observer
SAT	Subcutaneous adipose tissue
US	Ultrasound

**Parameters and variables:**

$m$	Body mass, in kg
$h$	Body height (stature) in m
$s$	Sitting height, in m
BMI	Body mass index: $BMI=m/h^2$ , in $kgm^{-2}$
$MI_1$	Mass index: $MI_1=0.53\cdot m/(hs)$ , in $kgm^{-2}$
$d$	SAT thickness measured by an individual observer at a given site, in mm (this is the average of the distances measured within the region of interest)
$D$	Sum of SAT-thicknesses measured by an individual observer at all eight sites in a given participant, in mm
$\delta$	measurement deviation of an individual observer from the mean of the three observers at a given site in a given athlete, in mm
$\delta_{rel}$	$\delta_{rel}=100\cdot\delta/d_{MEAN}$ , in [%]
$\Delta$	Deviation of the sum of eight sites measured by an individual observer from the mean of the sums of the three observers in a given athlete, in mm
$\Delta_{rel}$	$\Delta_{rel}=100\cdot\Delta/D_{MEAN}$ , in [%]
EXCL	Excluded; indicates that the fibrous structures embedded in the SAT are not included in the thickness value.
INCL	Included; indicates that the fibrous structures are included
$c$	speed of sound

**Statistics:**

$N$	Number of values
ABS	Absolute value of a number
MEAN	Mean value
SD	Standard deviation
SEE	Standard error of estimate
ICC	Intraclass correlation coefficient
IQR	Interquartile range
$R^2$	Coefficient of determination
$\rho$	Spearman's rank correlation coefficient (Spearman's rho)

**Ultrasound sites:**

UA	Upper abdomen
LA	Lower abdomen
ES	Erector spinae
DT	Distal triceps
BR	Brachioradialis
FT	Front thigh
LT	Lateral thigh
MC	Medial calf
EO	External oblique

## **APPENDIX**

### **Ad Part A of the (printed) main publication: Ultrasound technique and accuracy**

#### **Important points for avoiding errors and for standardising the US technique:**

1. Besides setting the sound speed correctly, it is also important to set all ultrasound (US) imaging parameters that determine the image quality adequately for a given anatomical structure. For example, using a too high gain, inadequate time-gain-compensation, inadequately positioned foci, or too low frequency, would broaden the borders and reduce image contrast. This would also decrease substantially the accuracy of tissue border detection.
2. The marker on one side of the linear US probe (a linear probe is necessary for accuracy reasons) is always directed upwards (cranially) or upwards-and-to-the-left. This corresponds to the usual application of diagnostic US probes in medicine.
3. Measurements are usually made on the right side of the participant's body. The middle of the probe is placed exactly above the landmarked site and held perpendicular to the skin. The investigator's hand may contact the participant's body in order to stabilise and guide of the probe, but there must be a minimum distance of 5 cm between the support hand and the probe. Otherwise, the pressure might distort the fat profile.
4. Always use a thick layer of US gel (at least 3 to 5 mm, avoid any air bubbles) between the probe and the skin. In the image, a black band above the skin corresponds to this gel layer. This is vital for the assessment of the US image because it ensures that there is no pressure on the skin which would compress the subcutaneous adipose tissue (SAT) layer. If the image quality is not good enough, it can be useful to restart the imaging with a new layer of gel on the probe. During US imaging, check that a dark band of about 3 to 5 mm above the skin can be seen on the screen.
5. The light should be dimmed in the examination room and the general gain and the depth gain compensation should be set such that the US image of the SAT is very dark and only the structures of interest can be seen clearly. Too much gain would

result in displaying "noise" in addition to real objects and in a decrease of resolution. Using "contour enhancement" image processing may improve the clarity of tissue borders.

6. The borders of SAT should be clear to the investigator when capturing the US image. The SAT layer should appear dark in the US image (otherwise the gain is too high); eventually some light lines which correspond to fibrous structures can be seen embedded in the fat. The investigator has to make sure that the borders of the SAT (end of skin on the upper side and muscle fascia on the lower side of the SAT layer) are clearly visible as white bands without any interruption; otherwise the algorithm will not do the image segmentation correctly.

7. In case of doubt about the location of the muscle fascia (i.e. the lower border of the SAT), compress the SAT with the US probe in order to distinguish between SAT and the muscle; this is essential in such cases to avoid erroneous image evaluation (misinterpretation of intermediate fasciae, like Camper's fascia in the abdomen).<sup>14 15</sup> When borders are clear, start the imaging again with a new 5 mm layer of gel.

8. Image evaluation should be done soon after having captured the US image. In case this is not possible, all US systems permit text to be inserted onto the US image. This feature can be used to mark the fascia of the muscle underneath the SAT (to prevent misinterpretations later). Of course, such annotations must be outside the region of interest.

9. In case a vein appears in the US image (black band without any grey speckle), move the probe beside the vein. For example, at the brachioradialis (BR) site, the vena cephalica is sometimes in the field of view. This might erroneously lead to a measurement of the vein thickness instead of the SAT thickness.

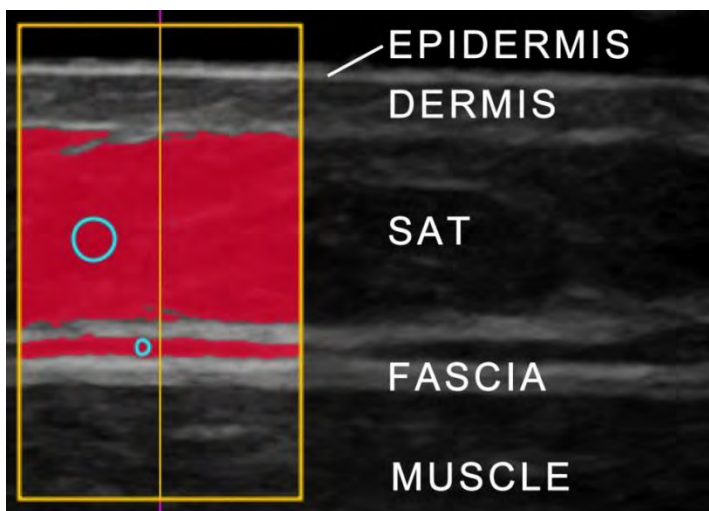

10. Establishing a reference data base requires a complete set of "meta information", including: an anonymous code for each athlete, gender, ethnicity, age ( $A$ ), body mass ( $m$ ), body height ( $h$ ), sitting height ( $s$ ), leg length ( $l$ ). Additional anthropometric measures can be added optionally. Athletes are characterised by their sport, sport discipline, performance level, training frequency and years of training.

### **Analysis of US thickness measurement accuracy:**

A typical US image from the site front thigh (FT) is shown in figure 7 in order to elucidate the resolution and accuracy limits of US imaging (18 MHz linear probe: GE L8-18i, operated in harmonic mode). The thicknesses  $d_{INCL} = 4.6$  mm,  $d_{EXCL} = 4.2$  mm, and the thickness of the dermis (1.0 mm) can be measured accurately with the evaluation software (FAT Software; rotosport.com) in the US image, but the value obtained for the epidermis thickness of 0.23 mm is too high; the thickness of the epidermis (measured microscopically) ranges typically between 0.08 to 0.10 mm. Accuracy of US distance measurements cannot reach microscopic levels. The

accuracy of tissue border detection is determined by: first, the axial US resolution limit (approximately equal to the wavelength used: about 0.1 mm, 0.2 mm, and 0.3 mm at 18, 9, and 5 MHz, respectively), and second, the sound speed ( $c$ ) used for calculating distances in a given tissue ( $d_{US}$ ):  $d_{US}=cT/2$  ( $T$  is the echo time). A sound speed of 1450 m/s was set in the inter-active evaluation algorithm for distance determination in SAT.<sup>17</sup>

The actual value might deviate slightly from the values determined in excised animal fat tissues (sound speed has not yet been measured in human SAT). A difference of 1% (e.g. 1465 m/s instead of 1450 m/s) would result in a measurement error of 0.1 mm in a 10 mm thick layer. In this case, this error is comparable to the border detection error (at 18 MHz). Conventional US machines use  $c = 1540$  m/s for all tissues: in a 10 mm SAT layer, this wrong speed of sound would result in an error of 0.6 mm, which cannot be ignored when accurate measurements are desired. The image analysis software used here allows setting of the correct speed of sound for all biological tissues.

**Figure 7:** The semi-automatic image segmentation and thickness measurement algorithm was applied to determine the SAT thickness at the site FT (red area). Within the region of interest (yellow frame), 156 thickness measurements resulted in an average value of  $d_{INCL} = 4.64$  mm and  $d_{EXCL} = 4.20$  mm ( $c_{FAT}$  was set to: 1450 m/s).<sup>17</sup> The mean thickness of the embedded fibrous structure is 0.44 mm. The US thickness measurements of the dermis and epidermis resulted in 0.96 mm and 0.23 mm, respectively ( $c_{SKIN}$  was set to 1540 m/s).<sup>17</sup> The two borders of the

epidermis cannot be resolved separately (just one white band of 0.23 mm mean thickness appears in the image). All US system parameters were adequately set to obtain optimal image resolution and contrast (gain, time gain compensation, foci, frequency, 18 MHz probe was used in harmonic mode).

In obese persons, SAT layers are several centimetres thick. There, accuracy is limited by incorrect sound speed rather than by US resolution. The *relative* distance measurement error would not increase with thickness; when sound speed is set correctly, it can even be smaller than in thin layers. For instance, when measuring a 100 mm thick SAT layer, it does not matter whether the borders are detected with a resolution of 0.1 or 0.3 mm (corresponding to 0.1% or 0.3% error, respectively). Therefore, it is also possible to obtain accurate thickness measurements in obese persons where lower US frequencies have to be used. The percentage deviation from the actual sound speed equals the relative distance measurement error because the technical border resolution error can be neglected in such thick layers.

## Ad Part B of the (printed) main publication: Selection and standardisation of ultrasound sites

Some of the new US sites are still in the vicinity of ISAK sites (DT, UA, LA, EO, FT, and MC) but with a much easier marking protocol, whereas some sites were added in order to receive SAT thickness information from body segments that were not included in the ISAK selection: ES for the trunk, LT for the fat depot at the lateral side of the thigh, and BR to represent the lower arm. The ISAK triceps site has been replaced by the distal triceps (DT) at which SAT thickness is more consistent than at the ISAK triceps site (where the curvature of the triceps muscle influences the SAT thickness). In order to sample SAT of the lower arm, the new site brachioradialis (BR) was introduced (instead of the ISAK biceps site, where SAT thickness is very thin in most athletes). Front thigh (FT) and medial calf (MC) remained close to the ISAK sites, but marking precision is much better with the new protocol.

The ISAK trunk sites caused major US imaging problems.<sup>14 15</sup> Subscapular was eliminated from the set of trunk sites because of the complex underlying anatomical structures and because of large SAT thickness gradients within the image. This site is replaced by the erector spinae (ES), where identification of SAT was always clear and thickness gradients were very small. The ISAK sites of abdominal, iliac crest, and supraspinale were also replaced for the same reasons. Three sites on the anterior side of the trunk were used in the inter-observer study described in part C: upper abdomen (UA), lower abdomen (LA), and external oblique (EO). For marking EO, the *anterior superior iliac spine (ASIS)* needs to be marked beforehand: this landmark is at the lower edge where the bone can just be felt. Lifting the right heel assists palpation of the most anterior point of the bone where the sartorius muscle originates (this can be traced when rotating the femur outward). For marking the EO site, it is important to find the ASIS point accurately. The ASIS point can also be used to measure the leg length (l). Most recently performed measurements in heavy weight athletes and in obese persons (manuscript in preparation) have shown that lateral thigh (LT) should be preferred to the external oblique (EO) site. In this group, marking EO was sometimes associated with difficulties because the bony landmarks were hard to identify and in obese persons folds of fat and skin prevented precise marking. Therefore, LT is suggested as one of the eight core sites, in place of EO. From this site, interesting information concerning fat patterning in different somatotypes and between men and women can be expected.<sup>26 27 29</sup>

When using sites in the abdomen region, the measurer has to be aware that an intermediate fascia (Camper's fascia) may be embedded in the SAT layer. In case of doubt about the lower border of the subcutaneous tissue, the US probe can first be put with some pressure on the skin. This enables the operator to distinguish visually between fat and muscle, since the fat is highly compressible and the border to the fascia of the clearly identifiable muscle becomes evident. After this pre-test, the US measurement should be resumed at this site with a new 5 mm layer of gel between the probe and the skin. It is of paramount importance to identify the muscle and its fascia without doubt, otherwise severe measurement mistakes will result.<sup>14 15</sup>

## Ad Part C of the (printed) main publication: Inter-observer reliability

### Statistics

The Kolmogorov-Smirnov test was used to test for normal distribution. Box-plots are used to visualise the distribution of each observer's measurement differences from their mean when absolute values of deviations are of interest (figures 6A and 6B), and when data are not normally distributed (figures 10A-D). Statistical analyses included the determination of standard errors of estimate (SEE), and linear regressions including coefficients of determination ( $R^2$ ) and significances. Inter-observer correlations were determined by calculating Spearman's rank correlation coefficients ( $\rho$ ), and intraclass correlation coefficients (ICC).

### Participants and observers

All participants (or their parents) completed a written consent form and had the opportunity to discuss methods and aims of the study with the investigators. Ethical approval was given by the Ethics Commission of the Medical University of Graz (20-295ex08/09). Data of participants are shown in table 3. The three observers performed the measurements in accordance with the site marking description and the US measuring and image evaluation technique as described in parts A and B of this publication. Two observers had performed US SAT measurements on more than 50 participants previously, while the third observer had undertaken a 2-day training course and had participated in a comparative test with five test persons.

**Table 3: Participants**

SAT patterning was measured by three observers in 12 national level athletes (females: 5 gymnasts, 1 swimmer; males: 4 gymnasts, 2 swimmers); age: 19.5 ( $\pm 4.3$ ) years,  $h = 1.70$  ( $\pm 0.12$ ) m,  $s = 0.90$  ( $\pm 0.06$ ) m,  $m = 64.1$  ( $\pm 15.0$ ) kg, BMI = 21.8 ( $\pm 2.4$ ) kgm<sup>-2</sup>, MI<sub>1</sub> = 21.8 ( $\pm 2.3$ ) kgm<sup>-2 34 12 31</sup>.

PARTICIPANT	age [y]	sex	$h$ [m]	$s$ [m]	$m$ [kg]	BMI	MI <sub>1</sub>
1	18	m	1.698	0.862	60.0	20.8	21.7
2	19	m	1.664	0.909	61.7	22.3	21.6
3	15	f	1.540	0.812	43.1	18.2	18.3
4	19	m	1.895	0.999	84.8	23.6	23.7
5	22	m	1.773	0.918	66.3	21.1	21.6
6	26	m	1.733	0.958	73.2	24.4	23.4
7	16	f	1.562	0.836	46.7	19.1	19.0
8	20	f	1.734	0.934	61.3	20.4	20.1
9	17	f	1.635	0.869	56.0	21.0	20.9
10	18	f	1.704	0.894	59.6	20.5	20.7
11	29	m	1.908	1.009	97.0	26.6	26.7
12	15	f	1.580	0.847	59.4	23.8	23.5

Anthropometric data include: body mass ( $m$ ), body height ( $h$ ), sitting height ( $s$ ) - measured in fully stretched position (compare to figure 1C), body mass index ( $BMI=m/h^2$ ), and the mass index ( $MI_1$ ). The  $MI_1$  considers individual sitting height:  $MI_1 = 0.53 m/(hs)$ ; for persons with an average relative sitting height (i.e. a Cormic index of  $C=s/h=0.53$ ), the BMI equals the MI, for persons with long legs, the MI is higher than the BMI.<sup>3 4 12 31</sup>  $MI_1$  values differed less than  $1 \text{ kgm}^{-2}$  in this group of athletes. Leg length is measured in standing position from the floor to the anterior superior spine (ASIS; see, appendix, part B). In the standardised SAT measurement protocol, athletes are additionally characterised by their sex, ethnicity, sport, discipline, performance level, training volume per week, and years of training.

### **Reasons for suggesting the site lateral thigh instead of external oblique:**

The lateral thigh (LT) site avoids marking problems that can occur at EO, particularly for heavy athletes and in participants with thick SAT layers. LT should, therefore, replace EO in future investigations. EO was used in this study because it is situated close to the ISAK site *supraspinale*. However, marking of EO necessitates the accurate identification of two anatomical bony landmarks, whereas all other sites do not. This may introduce a reduced precision, particularly for heavy athletes and obese persons. Preliminary results (this research is in progress) obtained with overweight persons indicate that thick layers of SAT do not cause noticeable measurement problems, except for the EO site. It is also useful to replace this site for athletes as the SAT is extremely thin in most cases (the mean contribution of EO to the average SAT thickness sum of the 12 athletes was only 6%). The low SAT thicknesses at EO (mean  $d_{INCL}$  in the 12 athletes was 1.8 mm, mean  $d_{EXCL}$  was 1.5 mm) can result in comparatively large relative errors  $\delta/d$ . The athletes in tables 2 and 4 are ordered according to their sum of SAT thicknesses ( $D_{INCL}$ ); this order does not change when the EO values are not considered. For these reasons, and because interesting information concerning fat patterning in different somatotypes and between men and women can be expected,<sup>27 29</sup> EO should be replaced by LT in the core set of sites.

## Additional results

### Sums of SAT thicknesses $D_{EXCL}$ measured by three observers:

Figure 8 shows the results of thickness sums when fibrous structures were not included in the thickness measurements (according data can be found in table 4).

**Figure 8: Sums of thicknesses from eight sites measured by the three observers in 12 athletes.**

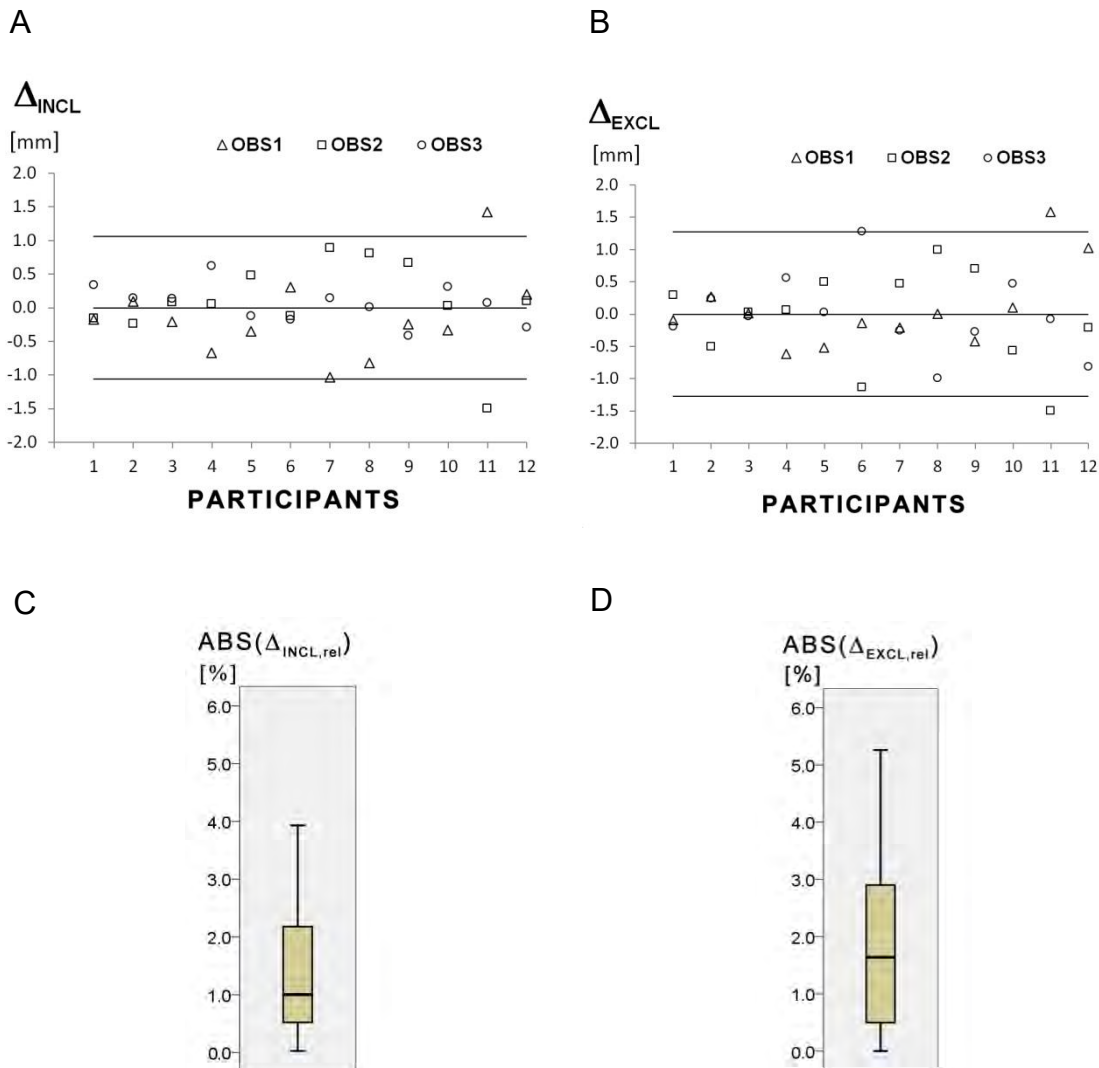

The sums  $D_{EXCL}$  of the individual observers (in a given participant) are displayed over the mean value of the three observers. Statistics for sums of SAT thicknesses with the fibrous structures excluded ( $D_{EXCL}$ ):  $R^2 = 0.997$  ( $p < 0.01$ ),  $SEE = 0.66$  mm,  $ICC = 0.996$  (lower 95% confidence limit: 0.990; upper 95% confidence limit: 0.999).

**Table 4: SAT thickness sums with fibrous structures excluded ( $D_{EXCL}$ ), means of sums ( $D_{EXCL,MEAN}$ ), and differences ( $\Delta_{EXCL} = D_{EXCL} - D_{EXCL,MEAN}$ ) (see figures 8 and 9B).**

PARTICIPANT	$D_{EXCL, MEAN}$	$D_{EXCL}$			$\Delta_{EXCL}$

## Observer differences from the mean:

Figures 9A and B show the differences of the individual observer's sums from their mean. Figure 9C and D show the relative observer differences in percent of  $D_{INCL,MEAN}$  and  $D_{EXCL,MEAN}$ .

**Figure 9: Observer differences from the mean.**

Three observer measurements of the sums from the eight sites in each of the 12 athletes (N=36).

**A.:** The differences of the individual observer's sums from the means  $\Delta_{INCL} = D_{INCL} - D_{INCL,MEAN}$  is shown for all 12 athletes (compare to table 2). The 12 athletes are ordered according to increasing values of  $D_{INCL}$ . SD is 0.54 mm. 95% of values are between upper and lower horizontal lines ( $\pm 1.96 \cdot SD$ ). Data is normally distributed.

**B.:** The differences of the individual observer's sums from the means of the three observers.  $\Delta_{EXCL} = D_{EXCL} - D_{EXCL,MEAN}$  is shown for all 12 athletes (compare to table 4). SD is 0.65 mm. 95% of values are between upper and lower horizontal lines ( $\pm 1.96 \cdot SD$ ). Data is normally distributed.

**C.:** Relative observer deviations in percent of  $D_{INCL,MEAN}$ :  $\Delta_{INCL,rel} = 100 \cdot ABS(\Delta_{INCL}) / D_{INCL,MEAN}$ . Median: 1.0%; maximum: 3.9%;  $D_{INCL,MEAN}$  ranged in the group of athletes from 10.2 mm to 51.2 mm.

**D.:** Relative observer deviation in percent of  $D_{EXCL,MEAN}$ :  $\Delta_{EXCL,rel} = 100 \cdot ABS(\Delta_{EXCL}) / D_{EXCL,MEAN}$ . Median was 1.6%; maximum: 5.3%;  $D_{EXCL,MEAN}$  ranged from 7.3 mm to 46.7 mm.

A

B

C

D

**Figure 10: Observer differences from the mean at the individual eight sites.**

Absolute values  $ABS(\delta)$  are used. Number of comparisons at each of the eight sites:  $N=36$  (twelve athletes were measured by three observers).

**A:** Absolute thickness value differences from the mean  $ABS(\delta_{INCL})$  for each of the eight sites. For characteristic box plot values see table 5A.

**B:**  $ABS(\delta_{EXCL})$ , analogously to A (compare to table 5B).

**C:** Absolute thickness value differences from the mean  $ABS(\delta_{INCL})$  for all eight sites together. Median is 0.12 mm; 95% of values are below 0.58 mm.

**D:** Analogously to C, here for  $ABS(\delta_{EXCL})$ . Median is 0.12 mm; 95% of values are below 0.50 mm.

Figures 10A and B show the absolute values (ABS) of observer deviations at each of the eight sites. The deviation  $\delta$  is the individual observer value  $d$  minus the mean of the three observer values  $d_{\text{mean}}$  at the given site. The number of comparisons of  $\text{ABS}(\delta)$  in each of the eight box plots was 36 (12 athletes were investigated by three observers).  $\text{ABS}(\delta_{\text{INCL}})$  refers to SAT thickness values with the fibrous structures included, and  $\text{ABS}(\delta_{\text{EXCL}})$  refers to SAT thickness values without fibrous structures. Tables 5A and B present the statistical characteristics related to the figures 10A and 10B. The deviations  $\delta$  were small in most cases: Medians ranged between 0.09 mm and 0.23 mm, 95% percent of all  $\text{ABS}(\delta_{\text{INCL}})$  values (N=288) were below 0.58 mm, and 95% of  $\text{ABS}(\delta_{\text{EXCL}})$  values were below 0.50 mm (compare to figures 10C and 10D).

The deviations relative to the mean thicknesses  $\delta_{\text{INCL,rel}}=100 \cdot \text{ABS}(\delta_{\text{INCL}})/d_{\text{INCL,MEAN}}$ , and  $\delta_{\text{EXCL,rel}}=100 \cdot \text{ABS}(\delta_{\text{EXCL}})/d_{\text{EXCL,MEAN}}$  can become large at sites where the biologically given thickness variation (in the close surrounding of the centre of the site) is comparable to the mean thickness in this area. This holds particularly true for very thin and inconsistent SAT layers. Large percentage deviations can also occur when, in very lean persons, the SAT thickness reaches the lower limit of the resolution of US (0.1 to 0.3 mm, depending on probe frequency). But such extremely thin fat layers at individual sites do not contribute substantially to the sum of SAT thicknesses.

**Table 5: Characteristic values of box plots in figures 10A and 10B:**  
Absolute values of deviations from the mean at given sites are used.

A: Measurement deviations (fibrous structures included)	ABS( $\delta_{\text{INCL}}$ ) [mm]

## Inter-observer correlation matrix:

In table 6, inter-observer Spearman's rank correlation coefficients ( $\rho$ ) are shown. Correlations at each individual site (three observers investigated 12 athletes,  $N=36$ ), and for all eight sites summarised as well ( $N=288$ ). At individual sites,  $\rho$  values (values above the diagonal in table 6 correspond to  $d_{INCL}$ ) ranged from 0.88 to 0.99, and for all sites all three  $\rho$  values were 0.98. The  $\rho$  values below the diagonal refer to the measurements of  $d_{EXCL}$ : correlation coefficients ranged from 0.91 to 0.99 at individual sites, and from 0.98 to 0.99 for all sites together.

**Table 6: Inter-observer correlation matrices**

Inter-observer Spearman's rank correlation coefficients ( $\rho$ ) of observers OB1, OB2, and OB3 are presented for each individual site ( $N=36$ ) and for all sites summarised as well ( $N=288$ ). **Bold numbers** above the main diagonals in the matrices represent the  $\rho$  values corresponding to SAT thicknesses  $d_{INCL}$ , and numbers below the diagonal refer to  $d_{EXCL}$ .

## Comparison of this inter-observer study (using the new set of sites) to a previous study (where ISAK sites were used):

Figures 5 and 8 show the sums of thicknesses  $D$  measured by the three observers, and differences  $\Delta$  of the sums (to the mean of the observers'  $D_{MEAN}$ ) are given in tables 2 and 4 and in figures 6A-B and 9A-D. Most (95%) of the 36 sums  $D_{INCL}$  obtained by the three observers in the 12 athletes deviated less than 1.0 mm (figure 9A), and for  $D_{EXCL}$ , 95% of differences were less than 1.3 mm (figure 9B). The medians (of the absolute values of deviations) were:  $ABS(\Delta)$ : 0.24 mm (1.0% of  $D_{INCL,MEAN}$ ) and 0.46 mm (1.6% of  $D_{EXCL,MEAN}$ ), respectively (compare to figures 6A and 6B, and 9C and 9D). Only two outliers occurred (1.50 mm and 1.43 mm) which resulted from an erroneous US image of one of the observers at the abdomen site: the Camper's fascia had erroneously been identified as the lower border of SAT, instead of the muscle fascia.

The reduction of outliers is substantial when compared to the results described in a previous study.<sup>15</sup> In this previous study, which used the ISAK sites, only 89% of images could be evaluated (because 51 images out of a total of 456 were unclear): this was partly because the anatomical structures underneath the ISAK sites were complex and difficult to interpret, and partly because the US SAT measurement technique and training program have been further refined. The detailed methodical description and the definition of the new US sites are given in part B of the main text and in parts A and B of the appendix. In the previous inter-observer study,<sup>15</sup> 19 grossly incorrect measurements occurred; nine errors because images were not sufficiently clear (in addition to the 51 images that were excluded ex ante), and 10 due to misinterpretations of Camper's fascia. In the study presented here, all images (288) could be evaluated and there was only one erroneous measurement.

In both inter-observer comparison studies, precision tended to be better when fibrous structures were included in the distance measurements. This can be explained because for  $d_{EXCL}$  measurements several borders of SAT have to be determined by means of the interactive algorithm, whereas for determination of  $d_{INCL}$ , determination of just the upper and the lower border of SAT are sufficient. Validation studies will show whether  $d_{INCL}$  or  $d_{EXCL}$  has higher predictive value, and such studies will also clear whether or not a subset of the eight sites defined for patterning studies will be sufficient for total body fat assessment.
